Figure 6: The top 10 items by the expected weight  $\beta_i$  from three of the 100 components discovered by our algorithm for the New York Times data set.

## A Exploratory analysis

The fitted HPF model can be explored to discover latent structure among items and users and to confirm that the model is capturing the components in the data in a reasonable way. For example, in Figure 6 we illustrate the components discovered by our algorithm on the news articles in the New York Times. The illustration shows the top items—items sorted in decreasing order of their expected weight  $\beta_i$ —from three of the 100 components discovered by our algorithm. From these, we see that learned components both cut across and differentiate between conventional topics and categories. We find that multiple business-related topics (e.g., self help and personal finance) comprise separate components, whereas other articles that appear across different sections of the newspaper (e.g., business and regional news) are unified by their content (e.g., airplanes).

## B The variational algorithm

Given an observed matrix of user behavior  $y$ , we would like to compute the posterior distribution of user preferences  $\theta_{uk}$ , item attributes  $\beta_{ik}$ , user activity  $\xi_u$  and item popularity  $\eta_i$ ,  $p(\theta, \beta, \xi, \eta | y)$ . Our derivation of the variational algorithm for HPF makes use of general results about the class of *conditionally conjugate* models [11, 16]. We define the class, show that HPF is in the class, and then derive the variational inference algorithm.

**Complete conditionals.** Variational inference fits the variational parameters to minimize their KL divergence to the posterior. For the large class of conditionally conjugate models, we can easily perform this optimization with a coordinate-ascent algorithm, one in which we iteratively optimize each variational parameter while holding the others fixed. A *complete conditional* is the conditional distribution of a latent variable given the observations and the other latent variables in the model. A conditionally conjugate model is one where each complete conditional is in an exponential family.

HPF, with the  $z_{ui}$  variables described in Section 2.2, is a conditionally conjugate model. (Without the auxiliary variables, it is not conditionally conjugate.) For the user weights  $\theta_{uk}$ , the complete conditional is a Gamma,

$$\theta_{uk} | \beta, \xi, z, y \sim \text{Gamma}(a + \sum_i z_{uik}, \xi_u + \sum_i \beta_{ik}). \quad (5)$$

The complete conditional for item weights  $\beta_{ik}$  is symmetric,

$$\beta_{ik} | \theta, \eta, z, y \sim \text{Gamma}(a + \sum_u z_{uik}, \eta_i + \sum_i \theta_{uk}). \quad (6)$$

These distributions stem from conjugacy properties between the Gamma and Poisson. In the user weight distribution, for example, the item weights  $\beta_{ik}$  act as “exposure” variables [9]. (The roles are reversed in the item weight distribution.) We can similarly write down the complete conditionals for the user activity  $\xi_u$  and the item popularity  $\eta_i$ .

$$\xi_u | \theta \sim \text{Gamma}(a' + Ka, b' + \sum_k \theta_{uk}).$$

$$\eta_i | \beta \sim \text{Gamma}(c' + Kc, d' + \sum_k \beta_{ik}).$$

The final latent variables are the auxiliary variables. Recall that each  $z_{ui}$  is a  $K$ -vector of Poisson counts that sum to the observation  $y_{ui}$ . The complete conditional for this vector is

$$z_{ui} | \beta, \theta, y \sim \text{Mult}\left(y_{ui}, \frac{\theta_u \beta_i}{\sum_k \theta_{uk} \beta_{ik}}\right). \quad (7)$$

Though these variables are Poisson in the model, their complete conditional is multinomial. The reason is that the conditional distribution of a set of Poisson variables, given their sum, is a multinomial for which the parameter is their normalized set of rates. (See [20, 5].)

**Deriving the algorithm.** We now derive variational inference for HPF. First, we set each factor in the mean-field family (Equation 4) to be the same type of distribution as its complete conditional. The complete conditionals for the item weights  $\beta_{ik}$  and user weights  $\theta_{uk}$  are Gamma distributions (Equations 5 and 6); thus the variational parameters  $\lambda_{ik}$  and  $\gamma_{uk}$  are Gamma parameters, each containing a shape and a rate. Similarly, the variational user activity parameters  $\kappa_u$  and the variational item popularity parameter  $\tau_i$  are Gamma parameters, each containing a shape and a rate. The complete conditional of the auxiliary variables  $z_{uik}$  is a multinomial (Equation 7); thus the variational parameter  $\phi_{ui}$  is a multinomial parameter, a point on the  $K$ -simplex, and the variational distribution for  $z_{ui}$  is  $\text{Mult}(y_{ui}, \phi_{ui})$ .

In coordinate ascent we iteratively optimize each variational parameter while holding the others fixed. In conditionally conjugate models, this amounts to setting each variational parameter equal to the expected parameter (under  $q$ ) of the complete conditional.

<sup>4</sup> The parameter to each complete conditional is a function of the other latent variables and the mean-field family sets all the variables to be independent. These facts guarantee that the parameter we are optimizing will not appear in the expected parameter.

For the user and item weights, we update the variational shape and rate parameters. The updates are

$$\gamma_{uk} = \langle a + \sum_i y_{ui} \phi_{uik}, b + \sum_i \lambda_{ik}^{\text{shp}} / \lambda_{ik}^{\text{rte}} \rangle \quad (8)$$

$$\lambda_{ik} = \langle c + \sum_u y_{ui} \phi_{uik}, d + \sum_u \gamma_{ik}^{\text{shp}} / \gamma_{ik}^{\text{rte}} \rangle. \quad (9)$$

These are expectations of the complete conditionals in Equations 5 and 6. In the shape parameter, we use that the expected

<sup>4</sup>It is a little more complex than this. For details, see [16].

count of the  $k$ th item in the multinomial is  $E_q[z_{uik}] = y_{ui}\phi_{uik}$ . In the rate parameter, we use that the expectation of a Gamma variable is the shape divided by the rate.

For the variational multinomial the update is

$$\phi_{ui} \propto \exp\{\Psi(\gamma_{uk}^{\text{shp}}) - \log \gamma_{uk}^{\text{rte}} + \Psi(\lambda_{ik}^{\text{shp}}) - \log \lambda_{ik}^{\text{rte}}\}, \quad (10)$$

where  $\Psi(\cdot)$  is the digamma function (the first derivative of the log  $\Gamma$  function). This update comes from the expectation of the log of a Gamma variable, for example  $E_q[\log \theta_{uk}] = \Psi(\gamma_{uk}^{\text{shp}}) - \log \gamma_{uk}^{\text{rte}}$ .
